(July 3, 2002)

Let $H^{[N]} = H^{[d_1]} \otimes \dots \otimes H^{[d_n]}$ be a tensor product of Hilbert spaces and let τ_0 be the closest separable state in the Hilbert-Schmidt norm to an entangled state ρ_0 . Let $\tilde{\tau}_0$ denote the closest separable state to ρ_0 along the line segment from I/N to ρ_0 where I is the identity matrix. Following [1] a witness W_0 detecting the entanglement of ρ_0 can be constructed in terms of I, τ_0 and $\tilde{\tau}_0$. If representations of τ_0 and $\tilde{\tau}_0$ as convex combinations of separable projections are known, then the entanglement of ρ_0 can be detected by local measurements. Gühne *et. al.* in [2] obtain the minimum number of measurement settings required for a class of two qubit states. We use our geometric approach to generalize their result to the corresponding two qudit case when d is prime and obtain the minimum number of measurement settings. In those particular bipartite cases, $\tau_0 = \tilde{\tau}_0$. We illustrate our general approach with a two parameter family of three qubit bound entangled states for which $\tau_0 \neq \tilde{\tau}_0$ and we show our approach works for n qubits.

In [3] we elaborated on the role of a “far face” of the separable states relative to a bound entangled state ρ_0 constructed from an orthogonal unextendible product base. In this paper the geometric approach leads to an entanglement witness expressible in terms of a constant times I and a separable density μ_0 on the far face from ρ_0 . Up to a normalization this coincides with the witness obtained in [2] for the particular example analyzed there.

I. MOTIVATION AND NOTATION

An important question for quantum information theory is how to determine if a given state is entangled. Physically, one would like to do this using local measurements and classical communications. Testing for entanglement is closely related to Bell inequalities [4] and subsequent elaborations of Bell’s inequalities [5]. Recently other tests have been suggested, such as that in [6] which relies on the theory of positive operators and on eigenvalue estimation.

An alternate approach, which is experimentally realizable, is to define local correlated measurements motivated by some knowledge of the structure of ρ itself, and this approach has been elaborated in [2]. To describe the problem, we first define the mathematical context. Specifically, we assume we are working with n distinct systems so that ρ is represented as an $N \times N$ density operating on the tensor product Hilbert space $H^{[N]} = H^{[d_1]} \otimes \dots \otimes H^{[d_n]}$. The set D of such $N \times N$ densities operating on $H^{[N]}$ is a compact convex subset of the real Hilbert space M of $N \times N$ Hermitian matrices where the inner product is defined by $\langle A, B \rangle = \text{Tr}[A^\dagger B]$. (Since the matrices are assumed to be Hermitian, the notation “ $\dagger$ ” denoting the Hermitian conjugate appears to be redundant. However, we will have occasion to use the inner product for more general matrices.) The set of separable densities S is defined as the convex hull of the separable projections $\pi_1 \otimes \dots \otimes \pi_n$, where π_k is a projection on $H^{[d_k]}$. Since S is a compact convex subset of D one can test for entanglement by showing ρ is separated from S by a hyperplane in M [7]. Geometrically the idea is clear. Mathematically it reduces to finding a Hermitian matrix W with the property that $\text{Tr}(W\rho) < 0 \leq \text{Tr}(W\sigma)$ for every density σ in S . The existence of such a W is guaranteed by the general theory of convex sets in Hilbert spaces, and W is known in the quantum information literature as an “entanglement witness”. A nice introduction to the subject and an overview of some of the literature can be found in [8].

In the context of two qubits Gühne *et. al.* in [2] assume the general form of a two parameter family of densities ρ which includes a maximally entangled state ρ_0 . They construct an entanglement witness using the eigenvector of the partial transpose of ρ with the minimal (negative) eigenvalue and find that the resulting witness does not depend on either of the parameters. Since the separating hyperplane contains a face of the separable states, it is *optimal* in the sense that no witness detects a strictly larger set of entangled states. (See [9] for the definitions and [1] for an exposition related to the approach used in this paper.)

In [1], the authors showed how an entanglement witness W_0 sensing an inseparable ρ_0 can be constructed if one also knows the nearest separable state τ_0 :

$$\|\rho_0 - \tau_0\| = \inf \{\|\rho_0 - \sigma\| : \sigma \in S\}.$$

Since the norm is a continuous function and the set of separable densities is compact, τ_0 exists, although actually computing it is not an easy problem in general. The entanglement witness is defined by

$$W_0 = \tau_0 + c_0 I - \rho_0, \quad (1)$$

where I is the $N \times N$ identity matrix and

$$c_0 = \text{Tr}(\tau_0(\rho_0 - \tau_0)).$$

Details and examples of this construction are given in [1] where it is shown that W_0 is linked to the geometry via the induced inner product

$$\langle(\rho_0 - \tau_0), (\rho - \tau_0)\rangle \equiv \text{Tr}((\rho_0 - \tau_0)(\rho - \tau_0)) = -\text{Tr}(W_0\rho). \quad (2)$$

In particular the separating hyperplane contains the “nearest” face of S consisting of separable states σ such that $\sigma - \tau_0$ is orthogonal to $\rho_0 - \tau_0$. Equation (2) can be used to show that the extreme separable projections in the convex representation of τ_0 must lie in the hyperplane, and that if any separable σ in the nearest face has full rank then W_0 is optimal.

It was first shown in [10] that there is a neighborhood of the normalized identity or completely random state, $D_0 = (1/N)I$, in which every state is separable. Given that fact, it follows from another compactness argument that there is a nearest separable density to ρ_0 along the line segment $[D_0, \rho_0]$:

$$\tilde{\tau}_0 = (1 - s_0) D_0 + s_0 \rho_0 \quad (3)$$

with $0 < s_0 < 1$. While τ_0 and $\tilde{\tau}_0$ differ in general, in certain examples they are the same which simplifies the analysis. Thus we have the following general result.

Theorem 1 *Suppose ρ_0 is inseparable. Using the notation above, the Hermitian matrix*

$$W_0 = I \left(c_0 + \frac{1 - s_0}{N s_0} \right) + \tau_0 - \frac{1}{s_0} \tilde{\tau}_0$$

is an entanglement witness for ρ_0 and is optimal if the nearest face contains a separable density of full rank. $\square$

Thus if one knew the convex representations of τ_0 and $\tilde{\tau}_0$ in terms of tensor products of local projections, one could define specific coordinated local measurements that would experimentally detect the entanglement of ρ_0 via $\text{Tr}(\rho_0 W_0)$. Finding τ_0 and $\tilde{\tau}_0$ is in general difficult but can be done in a variety of special cases. The examples we present include those analyzed in [2] as well as a two parameter family of three qubit bound entangled densities for which τ_0 and $\tilde{\tau}_0$ differ. (A bound entangled state is entangled but has positive partial transposes.)

Another result in [2] is that three sets of coordinated local measurements is the minimum number required in their two qubit context and an explicit representation of the three measurements was given. It was also asserted that at least $d + 1$ such measurements would be required for a corresponding $d \times d$ system, but no suggestion for achieving that bound was provided. We show how the geometric approach to entanglement witnesses provides a unifying theme and leads to a concrete construction for the $d \times d$ case when d is prime.

II. TWO QUBITS

In the two qubit case, the use of the nearest separable density clarifies some of the methodology and suggests the generalization to the $d \times d$ case. Following ref. [2] we take

$$\rho = p\rho_a + (1 - p)\sigma. \quad (4)$$

ρ_a is defined by the state $a|00\rangle + b|11\rangle$, where a and b are real with $a^2 + b^2 = 1$, p is a parameter between 0 and 1, and σ is a density close to the normalized identity, $\|\sigma - D_0\| < \delta$. The density σ represents noise that is close to D_0 , the completely random state. The idea is to define a separating hyperplane W_0 based on $\rho_0 = \frac{1}{2}(|00\rangle + |11\rangle)(\langle 00| + \langle 11|)$ and investigate what inseparable states ρ are detected by W_0 .

It has been shown in a number of places that the closest separable state to ρ_0 is

$$\tau_0 = \frac{2}{3}D_0 + \frac{1}{3}\rho_0, \quad (5)$$

so that the roles of τ_0 and $\tilde{\tau}_0$ coincide. (References and details are given in [1].) One computes $c_0 = \text{Tr}(\tau_0(\rho_0 - \tau_0)) = \frac{1}{6}$, and then eq. (1) gives

$$W_0 = \frac{1}{3} \begin{pmatrix} 0 & 0 & 0 & -1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ -1 & 0 & 0 & 0 \end{pmatrix}. \quad (6)$$

This differs from the optimal witness found in [2] only because of the use of a different Bell state and is a special case of the general theorem above.

As an application we have the following result.

Lemma 1 *A sufficient condition that $\rho = p\rho_a + (1-p)\sigma$, where $\|\sigma - D_0\| < \delta$, is not separable is that*

$$\left(\frac{1 + 4\delta}{4ab + 1 + 4\delta} \right) < p.$$

Proof:

$$\begin{aligned} \text{Tr}(W_0\rho) &= p\text{Tr}(W_0\rho_a) + ((1-p))\text{Tr}(W_0D_0) + (1-p)\text{Tr}(W_0(\sigma - D_0)) \\ &= \frac{-2abp}{3} + \frac{1}{6}(1-p) + (1-p)\text{Tr}(W_0(\sigma - D_0)) \\ &\leq \frac{-2abp}{3} + \frac{1}{6}(1-p) + (1-p)\frac{2\delta}{3} \end{aligned}$$

where we have used the Cauchy-Schwarz inequality in the last step. Setting the final expression to be less than 0, we obtain the desired inequality. Note that if $\delta = 0$ and $a = 1/\sqrt{2}$ we obtain the well known sufficient condition $1/3 < p$ for inseparability of $p\rho_0 + (1-p)D_0$. $\square$

Having defined W_0 we need to show that the measurement can be effected by three types of coordinated local measurements. We combine eq.(1) and eq.(5) to obtain

$$W_0 = \frac{2}{3}I - 2\tau_0 \quad (7)$$

and then use the representation of τ_0 as a convex combination of six separable extreme points in the face of the states of S in the separating hyperplane:

$$\begin{aligned} \tau_0 &= \frac{1}{6} \left[\left(\frac{\sigma_0 + \sigma_z}{2} \otimes \frac{\sigma_0 + \sigma_z}{2} \right) + \left(\frac{\sigma_0 - \sigma_z}{2} \otimes \frac{\sigma_0 - \sigma_z}{2} \right) \right. \\ &\quad + \left(\frac{\sigma_0 + \sigma_x}{2} \otimes \frac{\sigma_0 + \sigma_x}{2} \right) + \left(\frac{\sigma_0 - \sigma_x}{2} \otimes \frac{\sigma_0 - \sigma_x}{2} \right) \\ &\quad \left. + \left(\frac{\sigma_0 + \sigma_y}{2} \otimes \frac{\sigma_0 - \sigma_y}{2} \right) + \left(\frac{\sigma_0 - \sigma_y}{2} \otimes \frac{\sigma_0 + \sigma_y}{2} \right) \right] \end{aligned} \quad (8)$$

Thus one takes coordinated local measurements along the x , y , and z axes of the Bloch sphere to compute $\text{Tr}(W_0\rho) = \frac{2}{3} - 2\text{Tr}(\tau_0\rho)$. As shown in [2], this is the minimal number of coordinated local measurements which are required.

III. THE $d \times d$ CASE.

The approach used above immediately generalizes to the bipartite $d \times d$ case when d is prime ($d \neq 2$): we take an entangled “base” state ρ_0 for which we can compute the nearest separable state τ_0 and thus W_0 . We again consider the family of densities $\rho = p\rho_a + (1-p)\sigma$, where σ is close to the state D_0 , and define

$$\rho_a = |\psi_a\rangle\langle\psi_a| \quad \text{where} \quad |\psi_a\rangle = \sum_{k=0}^{d-1} a_k |kk\rangle$$

with real a_k such that $\sum_k a_k^2 = 1$. ρ_0 is the state with $a_k = 1/\sqrt{d}$, and

$$\tau_0 = \frac{d}{d+1}D_0 + \frac{1}{d+1}\rho_0 \quad (9)$$

is the closest separable state. (See [11] for the general result and references.) Again, τ_0 coincides with $\tilde{\tau}_0$, simplifying the problem [1,12–14]. From eq.(1) the optimal witness for ρ_0 is $W_0 = \frac{2}{1+d}I - d\tau_0$, where $c_0 = \frac{d-1}{d(d+1)}$. The problem now reduces to finding analogues of the Pauli matrices which can be used to represent τ_0 as an appropriate convex combination of projections, as in eq.(8). Fortunately that analysis already has been done.

In ref. [15] the authors observed that the (real) Pauli matrices can be viewed as discrete Fourier transforms of four “computational” basis matrices. Using an analogous basis for $d \times d$ matrices and the corresponding discrete Fourier transform, one is able to define d^2 orthogonal unitary matrices

$$U_d \equiv \{S_u : u = (j, k), \quad 0 \leq j, k < d\}$$

where $S_e = S_{(0,0)}$ is the $d \times d$ identity. (These same matrices had been derived independently and in a different manner by Fivel [16] who used them in a study of Hamiltonians on a discrete state space. He also derived several of the properties we include below.) As with the two qubit case, one can define sets of tensor products of projections, and it turns out that τ_0 can be written as a convex combination of $d+1$ such sets in strict analogy with the representation in eq.(8). These $d+1$ sets of projections correspond to the coordinated local measurements required in [2] for local detection of entanglement of $d \times d$ states.

We briefly summarize the necessary properties of these d -level “spin” matrices and relegate proofs to the Appendix. By definition

$$S_{(j,k)} = \sum_{r=0}^{d-1} \eta^{jr} |r\rangle \langle r+k|$$

where addition is modulo d and $\eta = \exp(2\pi i/d)$.

$$\text{Tr} \left[S_{(j_1, k_1)}^\dagger S_{(j_2, k_2)} \right] = d \delta_{j_1, j_2} \delta_{k_1, k_2}$$

expresses orthogonality, and thus U_d is a basis for $d \times d$ matrices.

Using tensor products of the U_d spin matrices, we find that for prime d

$$\tau_0 = \frac{1}{d+1} \left[\frac{1}{d^2} \sum_{k=0}^{d-1} S_{k(d-k), 00} + \sum_{j=0}^{d-1} \left(\frac{1}{d^2} \sum_{k=0}^{d-1} S_{(kj)(kd-kj), kk} \right) \right], \quad (10)$$

where $S_{ij,kl} = S_{i,k} \otimes S_{j,l}$, and it remains to show that each of the k -summations can be written as a sum of tensor products of complete sets of projections. When d is odd and $u = (j, k) \neq (0, 0)$,

$$P_u(r) \equiv \frac{1}{d} \sum_{m=0}^{d-1} (\eta^r S_u)^m$$

is a (Hermitian) projection, and $\{P_u(r) : 0 \leq r < d\}$ is a complete set of orthogonal projections. If $u_j = (j, 1)$ and $v_j = (d-j, 1)$ for $0 \leq j < d$, then (surpressing the subscript on u_j and v_j)

$$\frac{1}{d^2} \sum_{k=0}^{d-1} S_{(kj)(kd-kj), kk} = \frac{1}{d} \sum_{r=0}^{d-1} P_u(r) \otimes P_v(d-r).$$

The first summation (10) has an analogous representation if $u = (1, 0)$ and $v = (d-1, 0)$.

This completes the proof: the entanglement witness W_0 can be realized in terms of the identity and a separable density which in turn can be written as convex combination of $d+1$ sums of tensor products of complete (local) projections. This attains the lower bound for the number of coordinated local measurements as asserted in [2].

As in the two qubit case, the entanglement witness W_0 detects entanglement for a range of densities of the form $\rho = p\rho_a + (1-p)\sigma$. The computation is similar to that for Lemma 1, and we omit the details.

Lemma 2 $\rho = p\rho_a + (1-p)\sigma$ is inseparable provided

$$\frac{1-p}{p} \left(1 - \frac{1}{d} + \delta \sqrt{2d(d-1)} \right) < \left(\sum_{k=0}^{d-1} a_k \right)^2 - 1$$

where $\|\sigma - D_0\| < \delta$. When $d = 2$, this reduces to the inequality in Lemma 1. $\square$

IV. A THREE QUBIT EXAMPLE

The geometric approach also works for a particular two parameter family of three qubits which have positive partial transforms but are inseparable. Since these densities are not generated by complete *UPB* sets, it is not clear that other techniques can be used to define an appropriate entanglement witness.

Let $-1/8 \leq c, d \leq 1/8$ and define the three qubit density matrix

$$\rho(c, d) = \begin{pmatrix} 1/8 & 0 & 0 & 0 & 0 & 0 & 0 & 1/8 \\ 0 & 1/8 & 0 & 0 & 0 & 0 & 1/8 & 0 \\ 0 & 0 & 1/8 & 0 & 0 & c & 0 & 0 \\ 0 & 0 & 0 & 1/8 & d & 0 & 0 & 0 \\ 0 & 0 & 0 & d & 1/8 & 0 & 0 & 0 \\ 0 & 0 & c & 0 & 0 & 1/8 & 0 & 0 \\ 0 & 1/8 & 0 & 0 & 0 & 0 & 1/8 & 0 \\ 1/8 & 0 & 0 & 0 & 0 & 0 & 0 & 1/8 \end{pmatrix}$$

It is convenient to identify $\rho(c, d)$ with the four vector $\langle d, c, 1/8, 1/8 \rangle$ defined by the negative diagonal. We will use this notation for densities with analogous structure. Further, it simplifies calculations to use $m = (c + d)/2$ and $t = (c - d)/2$, and we abuse notation by writing $\rho(m, t)$ for the same density and $\langle m - t, m + t, 1/8, 1/8 \rangle$ for its four vector. The following result is proved in [17] for analogous densities $\rho(c, d)$ for n qubits defined by the 2^{n-1} vector with equal numbers of c 's and d 's and 2^{n-2} entries of $1/2^n$, $\langle d, \dots, d, c, \dots, c, 1/2^n, \dots, 1/2^n \rangle$.

Proposition 1 $\rho(c, d)$ has positive partial transposes and is completely separable if and only if $c = d$ ($t = 0$). $\square$

In the $d \times d$ cases analyzed above, the line segment from D_0 to ρ_0 was orthogonal to the nearest separable face, and that property characterized τ_0 , the nearest separable density to ρ_0 . Unfortunately, as shown in [1], that perpendicularity is lost when one goes to three systems and the nearest separable state $\tilde{\tau}_0$ to ρ_0 on the line segment $[D_0, \rho_0]$ does not coincide with the closest separable state τ_0 . However, one can still take advantage of the geometry *provided* $\tilde{\tau}_0$ lies in the nearest separable face to ρ_0 .

To pursue this idea for $\rho(c, d)$, we need some additional notation. Without loss of generality we take $c > d$ so that $t > 0$, and let $\sigma_1 = \sigma_x$ and $\sigma_2 = \sigma_y$. Let σ_0 denote the 2×2 identity and define

$$P_{jkl}^{\pm} = \frac{1}{8} [\sigma_0 \otimes \sigma_0 \otimes \sigma_0 \pm \sigma_j \otimes \sigma_k \otimes \sigma_l] \quad (11)$$

where j, k , and l will take the values 1 or 2. It is an easy exercise to represent such a $P_{jkl}^{\pm}$ as an average of four projections and to confirm that

$$\begin{aligned} \rho(m, t) &= \left(\frac{1}{2} + 4m\right) P_{111}^+ + \left(\frac{1}{2} - 4m\right) P_{221}^- \\ &\quad + 4t (P_{212}^- + P_{122}^+) - 8t D_0. \end{aligned}$$

As it happens, a study of the $m = 0$ case is key to the analysis, and we take as a candidate for $\tilde{\tau}_0(0, t)$ the normalization of the first part of $\rho(0, t)$:

$$\tilde{\tau}_0(0, t) = \frac{1}{1 + 8t} \left[\frac{1}{2} (P_{111}^+ + P_{221}^-) + 4t (P_{212}^- + P_{122}^+) \right]. \quad (12)$$

$\tilde{\tau}_0(0, t)$ is obviously separable but not so obviously the last separable state on $[D_0, \rho(0, t)]$. We confirm that property later. To see if $\tau_0(0, t)$ lies in the same face as $\tilde{\tau}_0(0, t)$, we take normalized combinations of the four $P_{jkl}^{\pm}$ in the equations above and minimize the distance to $\rho(0, t)$, finding the separable density with four vector

$$\left\langle -\frac{t}{2}, \frac{t}{2}, \frac{1}{8} - \frac{t}{2}, \frac{1}{8} - \frac{t}{2} \right\rangle.$$

Using this for $\tau_0(0, t)$ we find $c_0(0, t) = \frac{t}{4}$ and $W_0(0, t) = \frac{t}{4} W_0$ where

$$W_0 = \begin{pmatrix} -1 & 0 & 0 & 0 & 0 & 0 & 0 & -2 \\ 0 & -1 & 0 & 0 & 0 & 0 & -2 & 0 \\ 0 & 0 & -1 & 0 & 0 & -2 & 0 & 0 \\ 0 & 0 & 0 & -1 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 & -1 & 0 & 0 & 0 \\ 0 & 0 & -2 & 0 & 0 & -1 & 0 & 0 \\ 0 & -2 & 0 & 0 & 0 & 0 & -1 & 0 \\ -2 & 0 & 0 & 0 & 0 & 0 & 0 & -1 \end{pmatrix}$$

These heuristics work splendidly, and we also find that W_0 detects the entanglement of all $\rho(c, d)$ with $d < c$. This is illustrated in fig.1 where the separating plane is shown. Of course, the geometry is more complicated because the hyperplane is not two dimensional. As t decreases to 0, $\rho(0, t)$ moves to the center of the line segment $[P_{111}^+, P_{221}^-]$. As t becomes negative ($d > c$), τ_0 and $\tilde{\tau}_0$ move onto a new plane where P_{212}^+ and P_{122}^- replace P_{212}^- and P_{122}^+ . Recall that D_0 lies at the center of $[P_{ijk}^+, P_{ijk}^-]$. The case $m \neq 0$ is easily visualized.

Proposition 2 *Let $d < c$. Then $\tau_0(m, t)$ with four vector $\langle m - \frac{t}{2}, m + \frac{t}{2}, \frac{1}{8} - \frac{t}{2}, \frac{1}{8} - \frac{t}{2} \rangle$ is the closest separable density to $\rho(m, t)$. W_0 is an entanglement witness for every density in $\{\rho(c, d) : -1/8 \leq d < c \leq 1/8\}$.*

Proof: Set $m = 0$ and let $\pi = \pi_1 \otimes \pi_2 \otimes \pi_3$ denote any separable projection. Since $Tr(W_0 \rho(0, t)) < 0$ by construction, it suffices to confirm that $Tr(W_0 \mu) \geq 0$. Defining $\pi_k = |\psi_k\rangle\langle\psi_k|$ where

$$|\psi_k\rangle = \begin{bmatrix} \cos \theta_k \\ e^{i\phi_k} \sin \theta_k \end{bmatrix},$$

we obtain

$$2Tr(W_0 \mu) = 2 - \sin(2\theta_1) \sin(2\theta_2) \sin(2\theta_3) C(\varphi_1, \varphi_2, \varphi_3) \quad (13)$$

where

$$C(\varphi_1, \varphi_2, \varphi_3) = \cos(\varphi_1 + \varphi_2 + \varphi_3) + \cos(\varphi_1 + \varphi_2 - \varphi_3) \\ + \cos(\varphi_1 - \varphi_2 + \varphi_3) - \cos(\varphi_1 - \varphi_2 - \varphi_3).$$

The phase angles φ_k can take any value while $0 \leq \theta_k \leq \pi/2$. Confirming that the right side of eq.(13) is non-negative is a familiar Bell-inequality computation and proves the assertion when $m = 0$. It follows from comments after eq.(2) that $\tilde{\tau}_0(0, t)$ has to lie in the separating plane and is thus the closest separable state to $\rho(0, t)$ along $[D_0, \rho(0, t)]$, justifying the notation and the assumption made earlier.

The generalization to non-zero m is straight-forward. Using the asserted form for $\tau_0(m, t)$, it's easy to check that $\tau_0(m, t)$ is separable, that $\rho(m, t) - \tau_0(m, t) = \rho(0, t) - \tau_0(0, t)$ and also that $c_0(m, t) = \frac{t}{4}$. It follows that $\tau_0(m, t)$ is the closest separable state to $\rho(m, t)$ and $W_0(m, t) = W_0(0, t)$, completing the proof. $\square$

From $\rho(m, t) = (1 + 8t)\tilde{\tau}_0(m, t) - 8tD_0$ and the form of $\tau_0(m, t)$ we can express the entanglement witness in terms of the identity and explicit separable states:

$$W_0(0, t) = t \left[\frac{5}{4}I - 2(P_{111}^+ + P_{221}^- + P_{212}^- + P_{122}^+) \right].$$

Again we have shown that local detection of entanglement can be defined using the explicit representations of τ_0 and $\tilde{\tau}_0$ as convex combinations of separable projections.

V. GENERALIZATION TO N QUBITS

In ref. [17] $\tilde{\tau}_0$ was computed for the ρ_0 generated from the n -qubit GHZ state defined by

$$\rho_0 = |\psi_0\rangle\langle\psi_0| \quad \text{where} \quad |\psi_0\rangle = \frac{1}{\sqrt{2}}(|\tilde{0}\rangle + |\tilde{1}\rangle),$$

and $\tilde{j} = (j, \dots, j)$. It was shown that

$$\tilde{\tau}_0 = (1 - s_0) D_0 + s_0 \rho_0 \quad (14)$$

$$= s_0 \Delta + (1 - s_0) Q \quad (15)$$

where $s_0 = 1/(2^{n-1} + 1)$, $\Delta = \frac{1}{2}(|\tilde{0}\rangle\langle\tilde{0}| + |\tilde{1}\rangle\langle\tilde{1}|)$, and Q is a matrix $2^n \times 2^n$ matrix with entries $1/2^n$ on the diagonal and in the upper and lower corners. It is clear that Δ is a convex combination of two separable states. In [17] Q was expressed in terms of 2^{n-1} separable states. In [1] we also computed τ_0 and it can be shown that τ_0 can be expressed as a convex combination of Δ and Q . This is another example of a case when $\tau_0 \neq \tilde{\tau}_0$ but both densities lie on the near face. Applying Theorem 1 the optimal entanglement witness can be written as

$$W_0 = aI - b\Delta - cQ \quad (16)$$

with a, b , and c positive. In the two qubit case this result reduces to eq.(6).

VI. FAR FACE CONSTRUCTIONS

There are cases when an entanglement witness can be defined in terms of the identity and a separable state without computing the nearest separable density explicitly. In [18] a technique is described for the construction of inseparable densities with positive partial transposes, using orthogonal unextendible product bases (*UPB*). This clever approach assumes a set of m separable orthonormal states $B = \{|\varphi_k\rangle, 1 \leq k \leq m\}$ where each $|\varphi_k\rangle$ is a tensor product of states in their respective Hilbert spaces and where the orthogonal space $B^\perp$ contains no separable projections. If $\mu_k = |\varphi_k\rangle\langle\varphi_k|$ and one defines

$$\mu_0 = \frac{1}{m} \sum_{k=1}^m \mu_k, \quad (17)$$

then

$$\rho_0 = \frac{N}{N-m} D_0 - \frac{m}{N-m} \mu_0$$

can be shown to be an inseparable density with positive partial transform. A number of examples of orthogonal *UPBs* are given in [18] and in subsequent papers such as [19] and [20]. The ideas in [2] also apply in this context and are illustrated there using the two qutrit example “*TILES*” of [18].

In [3] some consequences of the geometric structure implicit in this approach are developed. For example, it is clear from the equation above that D_0 lies on the line segment $[\mu_0, \rho_0]$. If one denotes by F_0 the face of the separable densities S containing μ_0 , then, in the context of the real Hilbert space M , F_0 is orthogonal to that line. It is shown in [8] by a compactness argument that there is a positive ϵ such that

$$0 < \frac{\epsilon}{m} = \inf \{Tr[\mu_0 \sigma], \sigma \in S\}$$

and thus that the face $G_0 \equiv \{\sigma \in S : Tr[\mu_0 \sigma] = \frac{\epsilon}{m}\}$ is non-empty. In this context it is shown in [3] that

$$0 < s_0 \equiv 1 - \frac{\epsilon N}{m} < 1.$$

A consequence of this approach is that a separating witness W_0 for ρ_0 can be defined using (1) with

$$\tau_0 = (1 - s_0) D_0 + s_0 \rho_0.$$

In this construction τ_0 is not necessarily separable but is defined by the intersection of $[\mu_0, \rho_0]$ and a hyperplane containing the “near face” G_0 . Since both ρ_0 and τ_0 can be written explicitly in terms of μ_0 , which is separable, then once ϵ is known we can again express the entanglement witness in terms of the identity I and a separable density whose convex representation is known:

$$W_0 = \frac{\epsilon N}{N-m} \left(\mu_0 - \frac{\epsilon}{m} I \right)$$

Thus, the required coordinated local measurements are defined explicitly by the original set B and there will be no more than m different settings. Geometrically W_0 is expressed in terms of the identity and μ_0 , which lives in the far

face F_0 , on the “other side” of D_0 from ρ_0 . In the special case discussed in [2], this is the same witness as derived there, up to a multiplicative constant.

Consider separable densities $\mu_b = \sum_k p_k \mu_k$ in the face F_0 that are also close to μ_0 . Let b denote the reciprocal of the largest of the coefficients p_k . Then it is easy to define inseparable densities

$$\rho_b = \frac{ND_0 - b\mu_b}{N - b}$$

with positive partial transposes that are on the boundary of the set of densities D and are close to ρ_0 . Moreover W_0 can also serve as an entanglement witness for these densities. In fact, using the same notation as above, one can get a “frustram” of states of the form

$$\rho = (1 - p)\sigma + p\rho_b$$

which lie in D on the ρ_0 side of the hyperplane defined by W_0 , provided

$$\frac{p(m - b)}{N - b} + \frac{1 - p}{N} + \frac{(1 - p)\delta}{\sqrt{m}} < \frac{\epsilon}{m} \quad (18)$$

where $\|\sigma - D_0\| < \delta$. We omit the details, repeating instead that the Euclidean geometry of M provides an extremely useful context for examining questions of this sort and that the use of eq.(1) gives a unifying geometric approach for constructing entanglement witnesses.

We should note that the effects of dropping the hypothesis that the states in B are orthogonal is also discussed in [3], and weaker conditions on the states in B are given which allow the construction above of inseparable states to be generalized. In particular, one can perturb the orthogonal *UPB* case, losing orthogonality but preserving enough of the structure to allow the analysis to go through. The cost of this generalization, however, is that the resulting states do not automatically have positive partial transposes.

VII. SUMMARY

In this paper we have used a geometric definition of an entanglement witness W_0 detecting an inseparable state ρ_0 to show that W_0 always has a representation leading to entanglement detection using coordinated local measurements. This approach gives essentially the same witnesses and the same coordinated local measurements as derived in [2] for their particular two qubit case. When coupled with the generalized “spin” matrices defined in [15], it also achieves the lower bound asserted in [2] for the number of coordinated local measurements for the analogous $d \times d$ case, at least when d is prime. We also illustrated the use of the geometry by applying the methodology to a two parameter family of three qubit bound entangled states for which τ_0 and $\tilde{\tau}_0$ differ. The strength of the geometrical approach is further illustrated by applying it to the n qubit case. In the case of inseparable densities constructed using orthogonal *UPBs*, the geometric approach also applies, but produces a representation using a “far face” separable density.

VIII. APPENDIX

By definition the $S_{(j,k)}$ “spin” matrix is defined as

$$S_{(j,k)} = \sum_{r=0}^{d-1} \eta^{jr} |r\rangle \langle r+k|$$

where addition is modulo d and $\eta = \exp(2\pi i/d)$. If u denotes (j,k) , then S_u has trace 0 unless u equals $e \equiv (0,0)$. Orthogonality follows from

$$\begin{aligned} \text{Tr} \left[S_{(j_1,k_1)}^\dagger S_{(j_2,k_2)} \right] &= \text{Tr} \left[\sum_r \sum_s \eta^{-j_1 r} \eta^{j_2 s} (|r+k_1\rangle \langle r|) (|s\rangle \langle s+k_2|) \right] \\ &= \text{Tr} \left[\sum_r \eta^{(j_2-j_1)r} |r+k_1\rangle \langle r+k_2| \right] \\ &= d\delta_{j_1,j_2} \delta_{k_1,k_2}. \end{aligned}$$

Similarly, one can calculate some useful relations such as $S_{0,1}S_{1,0} = \eta S_{1,0}S_{0,1}$, $S_{j,k} = (S_{1,0})^j (S_{0,1})^k$, $(S_{j,k})^m = \eta^{jkm(m-1)/2} S_{mj,mk}$, and $S_{j,k}^\dagger = \eta^{jk} S_{d-j,d-k}$. Unlike the Pauli matrices, the S_u are not necessarily Hermitian, but they are unitary and can play a role analogous to that played by the Pauli matrices.

Any $d \times d$ density α can thus be written as a linear combination of these spin matrices, and we have

$$\alpha = \frac{1}{d} \left[S_e + \sum_{u \neq e} s_u S_u \right]$$

where we use $u = (j, k)$ in

$$s_u = \text{Tr} [S_u^\dagger \alpha] = \sum_r \eta^{-jr} \alpha_{r,r+k}.$$

To represent a density such as τ_0 defined in eq.(9) on the tensor product space $H^{[d]} \otimes H^{[d]}$, we use the set of tensor products of the spin matrices as an orthogonal basis. A direct calculation or an invocation of eq.(16) of ref. [15] gives

$$\tau_0 = \frac{1}{d^2} \left[\frac{d}{d+1} S_{00,00} + \frac{1}{d+1} \sum_{k=0}^{d-1} \sum_{i=0}^{d-1} S_{i(d-i),kk} \right]$$

where $S_{ij,kl} = S_{i,k} \otimes S_{j,l}$. It is at this point that we require d be prime. Then for given i and $k \neq 0$ there is a unique j such that $i = jk \pmod{d}$, and we can rewrite τ_0 in the form

$$\begin{aligned} \tau_0 &= \frac{1}{d+1} \left[\frac{d}{d^2} S_{00,00} + \frac{1}{d^2} \sum_{i=0}^{d-1} S_{i(d-i),00} + \frac{1}{d^2} \sum_{k=1}^{d-1} \sum_{j=0}^{d-1} S_{(kj)(kd-kj),kk} \right] \\ &= \frac{1}{d+1} \left[\frac{1}{d^2} \sum_{k=0}^{d-1} S_{k(d-k),00} + \sum_{j=0}^{d-1} \left(\frac{1}{d^2} \sum_{k=0}^{d-1} S_{(kj)(kd-kj),kk} \right) \right]. \end{aligned}$$

It remains to show that each of the expressions involving a k -summation is a summation of tensor products of projections from a complete set of orthogonal projections. That is, each summation corresponds to correlated local measurements, and τ_0 is realized by $d+1$ such summations.

We begin by defining a complete set of projections in terms of the spin matrices, a construction which corresponds to that in the spin 1/2 context.

Lemma 3 (Reference [15]) *Let $d > 2$ be prime and let $e \neq u = (j, k)$. Then if*

$$P_u(r) \equiv \frac{1}{d} \sum_{m=0}^{d-1} (\eta^r S_u)^m = \frac{1}{d} \sum_{m=0}^{d-1} \eta^{mr} \eta^{jkm(m-1)/2} S_{mu},$$

$\{P_u(r) : 0 \leq r < d\}$ is a complete set of trace one, orthogonal (Hermitian) projections.

Proof: $P_u(r)$ has trace one since the only term with non-zero trace is the $m = 0$ term. From the definition

$$\begin{aligned} P_u(r) P_u(s) &= \frac{1}{d^2} \sum_{m=0}^{d-1} \sum_{n=0}^{d-1} \eta^{mr+ns} \eta^{jk[m(m-1)+n(n-1)]/2} S_{mu} S_{nu} \\ &= \frac{1}{d^2} \sum_{m=0}^{d-1} \sum_{n=0}^{d-1} \eta^{(m+n)r} \eta^{jk[m(m-1)+n(n-1)]/2} \eta^{jkmn} S_{(m+n)u} \eta^{n(s-r)}. \end{aligned}$$

Make the substitution $t = m + n$ in the last expression and collect terms to obtain

$$P_u(r) P_u(s) = \left(\frac{1}{d} \sum_{n=0}^{d-1} \eta^{n(s-r)} \right) \frac{1}{d} \sum_{t=0}^{d-1} \eta^{tr} \eta^{jkt(t-1)/2} S_{tu},$$

thereby obtaining both the orthogonality and $P_u(r) P_u(r) = P_u(r)$. Finally

$$\begin{aligned}
(P_u(r))^\dagger &= \frac{1}{d} \sum_{m=0}^{d-1} \eta^{-mr} (S_u^\dagger)^m = \frac{1}{d} \sum_{m=0}^{d-1} \eta^{-mr} (\eta^{jk} S_{-u})^m \\
&= \frac{1}{d} \sum_{m=0}^{d-1} \eta^{-mr+mjk+jkm(m-1)/2} S_{-mu} = \frac{1}{d} \sum_{n=0}^{d-1} \eta^{nr+jkn(n-1)/2} S_{nu} \\
&= P_u(r).
\end{aligned}$$

These steps actually introduce a factor of the form $\eta^{jkd(d-1)/2}$ which equals 1 for odd integers. However, if d is even and j and k are odd, $\eta^{jkd(d-1)/2} \neq 1$, and the proof must be modified. $\square$

Having defined complete sets of projections, we are ready for the final technical result.

Proposition 3 *Let $u_j = (j, 1)$ and $v_j = (d - j, 1)$ for $0 \leq j < d$. Then*

$$\frac{1}{d} \sum_{r=0}^{d-1} P_{u_j}(r) \otimes P_{v_j}(d - r) = \left(\frac{1}{d^2} \sum_{k=0}^{d-1} S_{(kj)(kd-kj),kk} \right).$$

If $x = (1, 0)$ and $y = (d - 1, 0)$, then

$$\frac{1}{d} \sum_{r=0}^{d-1} P_x(r) \otimes P_y(d - r) = \frac{1}{d^2} \sum_{k=0}^{d-1} S_{k(d-k),00}.$$

Proof: The proof is just a matter of navigating the notation. Suppressing the subscript,

$$\begin{aligned}
\frac{1}{d} \sum_{r=0}^{d-1} P_u(r) \otimes P_v(d - r) &= \frac{1}{d^3} \sum_{k,n} (S_u)^k \otimes (S_v)^n \sum_r \eta^{(k-n)r} \\
&= \frac{1}{d^2} \sum_k S_{ku} \otimes S_{kv} \eta^{[jk(k-1)/2 + (d-j)k(k-1)/2]} \\
&= \frac{1}{d^2} \sum_m S_{ku} \otimes S_{kv} = \frac{1}{d^2} \sum_{k=0}^{d-1} S_{(kj)(kd-kj),kk}
\end{aligned}$$

as required. The proof of the remaining assertion is similar, and we omit the details. $\square$
